Abstract

Local coupling between nitrogen fixation and denitrification in current biogeochemical models could result in a run-away feedback in open-ocean oxygen minimum zones (OMZs), eventually stripping OMZ waters of all fixed nitrogen. This feedback does not seem to operate at full strength in the ocean, as nitrate does not generally become depleted in open-ocean OMZs. To explore in detail the mechanism that prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific (ETSP), we develop a box model with fully prognostic cycles of carbon, nutrients, and oxygen in the upwelling region and its adjacent open ocean. Ocean circulation is calibrated with $\Delta^{14}\text{C}$ data of the ETSP. The sensitivity of the simulated nitrogen cycle to nutrient and oxygen exchange and ventilation from outside the model domain and remineralization scales inside an OMZ is analysed. For the entire range of model configurations explored, we find that the fixed-N inventory can be stabilized at non-zero levels in the ETSP OMZ only if the remineralization rate via denitrification is slower than that via aerobic respiration. In our optimum model configuration, lateral oxygen supply to the model domain required at rates sufficient to oxidize at least about a fifth of the export production in the model domain to prevent anoxia in the deep ocean. Under these conditions, our model is in line with the view of phosphate as the ultimate limiting nutrient for phytoplankton, and implies that for the current notion of nitrogen fixation being favored in N-deficit waters, the water column of the ETSP could even be a small net source of fixed-N.

1 Introduction

The oceanic fixed nitrogen (fixed-N) budget is an essential control on the potential of the ocean to sequester atmospheric CO_2 via the marine biological pump. Denitrification is generally recognized as a major loss of fixed nitrogen, whereas the balance of the global oceanic nitrogen budget remains controversial. Accordingly, estimates for the global oceanic fixed-N budget range from sources roughly balancing sinks (Gruber

and Sarmiento, 1997; Gruber, 2004; Eugster and Gruber, 2012) to a rather large net deficit between 140 and 234 Tg N yr⁻¹ (Codispoti et al., 2001; Galloway et al., 2004; Codispoti, 2007).

One of the main uncertainties in the global marine nitrogen budget is the extent of nitrogen loss via denitrification and anaerobic ammonium oxidation (anammox) in oxygen minimum zones (OMZs), located in tropical coastal upwelling regions. Coastal upwelling zones are often associated with very high primary production. Subsequent decomposition of sinking organic matter leads to high levels of oxygen consumption in subsurface waters. Under conditions of sluggish circulation, oxygen-poor source waters, or lack of exchange with oxygenated surface waters, OMZs can develop, usually at intermediate depths of about 200–700 m (Bethoux, 1989; Capone and Knapp, 2007). An OMZ is commonly defined as a water body with an O₂ concentration below 20 µmol L⁻¹ (Paulmier and Ruiz-Pino, 2009). The four major open-ocean OMZs are in the Eastern North Pacific (ENP), the Eastern Tropical South Pacific (ETSP), the Arabian Sea, and the Bay of Bengal. OMZs currently account for only about 8 % of the global ocean area but are thought to be responsible for 30–50 % of the total fixed-N loss (Gruber and Sarmiento, 1997; Codispoti et al., 2001; Dalsgaard et al., 2005; Paulmier and Ruiz-Pino, 2009).

Canfield (2006) used a simple steady-state box model of a coastal OMZ to show that a positive feedback between N₂ fixation and denitrification could strip the OMZ of all fixed nitrogen when N₂ fixation was permitted to restore the nitrate : phosphate ratio to Redfield proportions in the surface ocean. Observed concentrations of fixed-N (nitrate plus nitrite) in OMZ waters, however, typically range from about 15 to 40 µmol L⁻¹ (Codispoti and Richards, 1976; Codispoti and Packard, 1980; Morrison et al., 1998; Voss et al., 2001). A possible explanation for the relatively high nitrate concentrations even in the suboxic core of open-ocean OMZs could be low levels of nitrogen fixation in the overlying surface waters (Landolfi et al., 2013). However, recent interpretations of observed fixed-N deficits relative to the Redfield equivalent of phosphorus point to high rates of nitrogen fixation closely related to the upwelling of nitrogen-deficit waters along

Interactive Discussion

the South American coast (Deutsch et al., 2007). Although alternative explanations for these nutrient patterns have been proposed (Mills and Arrigo, 2010), direct measurements have confirmed the occurrence of nitrogen fixation in and above the OMZ of the ETSP (Fernandez et al., 2011). Global biogeochemical models also generally predict substantial rates of N_2 fixation in the nitrate-deficit waters of the upwelling region of the ETSP that, if not compensated by some ad-hoc slow-down of remineralization in suboxic conditions, lead to a complete draw-down of nitrate in the OMZ (Moore and Doney, 2007; Schmittner et al., 2008). The question of how non-zero nitrate concentrations can be maintained in the OMZ thus still awaits a mechanistic answer.

The computational efficiency of box models makes them suitable for sensitivity analysis requiring thousands of model evaluations. In spite of its simplicity, Canfield's (2006) box model is also able to capture the most important first-order interactions among ocean circulation, nitrogen fixation, denitrification, and OMZs. However, Canfield's model was limited in its power to investigate the influence of open ocean nutrients and oxygen conditions on the upwelling region, because its dynamics were restricted to the OMZ, where all biogeochemical tracers were prescribed in the surrounding waters. Based on Canfield's (2006) steady-state formulation with prescribed oxygen and nutrient concentrations at all depths outside the OMZ, we here present a fully prognostic box model of NO_3^- , PO_4^{3-} and O_2 cycles in a coastal upwelling region and an adjacent ocean basin. We employ this model to examine under which conditions the observed situation of an essentially complete drawdown of subsurface oxygen and an incomplete drawdown of nitrate can be reproduced for the case of the ETSP. Sensitivity experiments explore how nutrient exchange and oxygen ventilation from the southern boundary influence the nitrogen budget within the model domain.

By including a prognostic description not only of conditions within the OMZ, but also in the water surrounding it, we aim to represent local as well as spatially-separated feedbacks between the relatively small OMZ and the much larger open-ocean basin. The model describes net primary and export production by ordinary and N_2 -fixing phytoplankton, as well as aerobic and anaerobic remineralization. The latter is generally

Interactive Discussion

associated with nitrogen loss, commonly attributed to denitrification (Codispoti, 1995). Anammox has recently been suggested as another major pathway for fixed-N removal (Kuypers et al., 2005; Hamersley et al., 2007; Molina and Farías, 2009), but the relative contributions of anammox and denitrification are still a matter of debate (Ward et al., 2009; Bulow et al., 2010). In our model, we do not explicitly resolve the different inorganic nitrogen species and pragmatically consider all loss of fixed-N via anaerobic remineralization as denitrification. In Canfield's (2006) model, most of the physical model parameters were constrained by observations from suboxic upwelling zones in the Arabian Sea and the Eastern Tropical North and South Pacific. The physical dynamics of our model system is governed by vertical and horizontal mixing and advection, which are calibrated with $\Delta^{14}\text{C}$ data of the ETSP from GLODAP (Global Ocean Data Analysis Project, Key et al., 2004).

2 Model description

Figure 1 shows the model structure, consisting of five boxes representing an upwelling region and an adjacent ocean basin. The U box represents the upper upwelling region. The UM box is the underlying OMZ, where suboxia is expected to develop. The S box represents the surface ocean away from the upwelling zone. Below the S box sits the I box, which represents water of intermediate depth and exchanges water with UM. D is the deep box, which represents water deeper than 500 m. When the UM, I, or D boxes become suboxic, denitrification will ensue to remineralize the exported organic matter, causing a loss of fixed nitrogen (Denif).

Prognostic tracers represent NO_3^- , PO_4^{3-} , O_2 , ^{14}C and the biomass of ordinary and N_2 -fixing phytoplankton, respectively (Table 1). The rate of concentration change of a tracer (X_i) in box i is composed of physical transport, $\text{Transport}(X_i)$, and a sources-minus-sinks term, $\text{SMS}(X_i)$, which represents the effects of biotic processes, air-sea gas exchange and, in the case of ^{14}C , radioactive decay on the tracer concentration

(Eq. 1).

$$\frac{dX_i}{dt} = \frac{\text{Transport}(X_i) + \text{SMS}(X_i)}{V_i} \quad i \in [\text{U}, \text{S}, \text{UM}, \text{I}, \text{D}] \quad (1)$$

where U, S, UM, I and D refer to the model boxes defined above and V_i to the corresponding volumes (Fig. 1).

2.1 Transport model

Advection represents the large-scale circulation and is indicated in Fig. 1 by wide grey lines. L_U and L_S are the horizontal scales of the upwelling region and the open ocean, and H_U , H_{UM} and H_D refer to the thickness of the respective boxes. The volumes V_i of the boxes are defined in this 2-D model by $V_i = H_i \cdot L_i$. K_{US} , K_{UM} and K_H are the coefficients of mixing between different boxes. A and B represent the deep and shallow large-scale circulation. The upwelling intensity into box U is given by $A + B$. The tracer transport equations for the standard configuration are given in Appendix A (Eqs. A1–A5). All parameters are defined in Tables 4 and 5.

2.2 Biogeochemical model

The ecological model is composed of two phytoplankton types, ordinary phytoplankton, Phy, and nitrogen fixers, NF. The SMS terms for phytoplankton are then obtained as the difference between net primary production (NPP) and mortality (M):

$$\text{SMS}(\text{Phy}_i) = (\text{NPP}^{\text{Phy}_i} - M^{\text{Phy}_i} \cdot \text{Phy}_i) \cdot V_i \quad i \in [\text{U}, \text{S}] \quad (2)$$

$$\text{SMS}(\text{NF}_i) = (\text{NPP}^{\text{NF}_i} - M^{\text{NF}_i} \cdot \text{NF}_i) \cdot V_i \quad i \in [\text{U}, \text{S}] \quad (3)$$

Both types require phosphate, whereas nitrate is required in addition to phosphate only by Phy, and NF can fix N_2 as long as PO_4^{3-} is available. Growth of ordinary phytoplankton is described by a Liebig-type dependence on the nitrate and phosphate limitation

terms (Eq. 4),

$$\text{NPP}^{\text{Phy}_i} = \mu \cdot \min \left(\frac{N_i}{N_i + N_h}, \frac{P_i}{P_i + P_h} \right) \cdot \text{Phy}_i \quad i \in [\text{U}, \text{S}] \quad (4)$$

$$\text{NPP}^{\text{NF}_i} = \mu_{\text{NF}} \cdot \frac{P_i}{P_i + P_h} \cdot \text{NF}_i \quad i \in [\text{U}, \text{S}] \quad (5)$$

5 where i is the model box, μ and μ_{NF} are the maximum growth rates of Phy_i and NF_i respectively. N_i and P_i are nitrate and phosphate concentrations, and N_h and P_h are half-saturation concentrations for nitrate and phosphate.

N_2 fixers are given a lower maximum growth rate (μ_{NF} , Eq. 5), which is 1/3 of the maximum growth rate of ordinary phytoplankton (μ), to account for the high cost of nitrogen fixation (La Roche and Breitbarth, 2005). The dependence of NF on iron is not explicitly considered in this model (Mills et al., 2004). Both Phy and NF use nitrogen and phosphorus in the Redfield ratio of 16 : 1 (Redfield et al., 1963). Phytoplankton mortality can be linear or quadratic in Phy and NF depending on the model configuration. Sensitivity experiments are also performed with a configuration where N_2 fixation is inhibited by NO_3^- , but overall results are found to be virtually unchanged (Appendix D).

Dead phytoplankton is immediately remineralized in the surface layer and underlying boxes according to the respective remineralization fraction f_i of box i . Remineralization occurs preferentially via aerobic respiration, with anaerobic remineralization and the associated nitrogen loss setting in only when all O_2 has been consumed by aerobic respiration. Phytoplankton growth and aerobic remineralization together with denitrification and, once all inorganic nitrogen is consumed, remineralization via sulfate reduction define the SMS terms of the nitrogen and phosphorus cycles:

$$\text{SMS}(\text{N}_i) = -\text{NPP}^{\text{Phy}_i} \cdot V_i + \text{Rem}_i^{\text{N}} - \text{Denif}_i \quad (6)$$

$$\text{SMS}(\text{P}_i) = -\frac{(\text{NPP}^{\text{Phy}_i} + \text{NPP}^{\text{NF}_i}) \cdot V_i}{r_p} + \text{Rem}_i^{\text{P}} \quad (7)$$

where the remineralization (Rem) and denitrification (Denif) terms are defined in Appendix B.

O_2 is set constant in the surface ocean boxes U and S, which are in immediate contact with the atmosphere, but varies as a function of transport and respiration in the UM, I and D boxes. Thus, the aerobic respiration terms (Res_i) are only needed in the interior boxes UM, I and D:

$$SMS(O_{2i}) = -Res_i \quad i \in [UM, I, D] \quad (8)$$

where Res is defined in Appendix B (Eq. B10). Note that aerobic respiration will, in general, also take place in anoxic model boxes, where it utilizes the O_2 transported from adjacent boxes, before anaerobic respiration starts. All model runs are initialized with O_2 , NO_3^- and PO_4^{3-} annual data from the World Ocean Atlas 2009 (Garcia et al., 2010a, b), averaged over the regions indicated in Table 2.

2.3 Model calibration

In the present work, the prescribed transport among the different boxes in terms of advection and mixing was calibrated by fitting the modeled $\Delta^{14}C$ distribution to the GLO-DAP “pre-bomb” $\Delta^{14}C$ distribution of the Eastern Tropical South Pacific (Key et al., 2004; Table 2). The ^{13}C fractionation-corrected ratio of $^{14}C/^{12}C$, $\Delta^{14}C$, is commonly used in ocean modeling to evaluate and calibrate model physics (Toggweiler et al., 1989; Shaffer and Sarmiento, 1995), because it tends to cancel the effect of the biotic downward transport of ^{14}C with the rain of organic particles produced by marine organisms. The $\Delta^{14}C$ distribution in our model is simulated with the help of a water-mass tracer, $\widehat{\Delta^{14}C}$, which is converted to $\Delta^{14}C$ units as follows:

$$\Delta^{14}C = 1000(\widehat{\Delta^{14}C} - 1) \text{‰} \quad (9)$$

The ^{14}C dynamics in the model includes input from the atmosphere at the sea surface and radioactive decay with decay rate $\lambda = 1.21 \times 10^{-4} \text{ yr}^{-1}$ within the model domain.

Interactive Discussion

The SMS term for $\widehat{\Delta^{14}\text{C}}$ is thus given by:

$$\text{SMS}(\widehat{\Delta^{14}\text{C}}_i) = \left(\frac{g_i(\widehat{\Delta^{14}\text{C}}_a - \widehat{\Delta^{14}\text{C}}_i)}{H_i} - \lambda \widehat{\Delta^{14}\text{C}}_i \right) \cdot V_i \quad i \in [\text{U}, \text{UM}, \text{S}, \text{I}, \text{D}] \quad (10)$$

where $\widehat{\Delta^{14}\text{C}}_i$ is the value of $\widehat{\Delta^{14}\text{C}}$ in box i , $\widehat{\Delta^{14}\text{C}}_a$ is atmospheric $\widehat{\Delta^{14}\text{C}}$, and the gas exchange rate $g_i = 0$ for $i \in [\text{UM}, \text{I}, \text{D}]$. We assume that the $\Delta^{14}\text{C}$ of the preindustrial atmosphere, $\Delta^{14}\text{C}_a$, is 0‰; therefore, the atmospheric $\widehat{\Delta^{14}\text{C}}_a$ is 1. Model configurations with an open southern boundary also include ^{14}C exchange with the adjacent subtropical ocean. We also investigate how sensitive our main conclusions are to the uncertainty in the $\Delta^{14}\text{C}$ data. Table 2 shows the $\Delta^{14}\text{C}$ values used for the calibrations of the different model configurations. Transport and SMS terms for ^{14}C constitute a system of 5 linear equations in 7 parameters, including the transport parameters A , B , K_{US} , K_{UM} , K_{H} and the air–sea ^{14}C exchange coefficients for g_{U} and g_{S} . After setting g_{U} and g_{S} , the 5 equations can be inverted to solve for the transport parameters. A detailed description of the inversion scheme is provided in Appendix C.

2.4 Model configurations

Above transport and biogeochemical formulations define the standard (STD) configuration, where phytoplankton mortality is formulated by a linear term with constant coefficient ($M^{\text{Phy}_i} = M^{\text{NF}_i} = M$). In the STD configuration, the above transport and biogeochemical models are applied without exchange with the southern boundary. Fixed fractions f_i of net primary production in U and S are remineralized in the U, UM, S and I boxes, with the remainder being remineralized in D (Fig. 1). Nutrient regeneration is assumed to be instantaneous.

In order to investigate the relationships between the different biotic and physical processes and the nitrogen cycle in an OMZ, we introduce eight additional model configurations (Table 3): (1) In the QM configuration, a quadratic form is adopted for the

mortality of both ordinary phytoplankton and nitrogen fixers:

$$M^{\text{Phy}_i} = M_q \text{Phy}_i \quad M^{\text{NF}_i} = M_q \text{NF}_i \quad (11)$$

Possible mechanisms represented by a quadratic mortality term are viral lysis, phytoplankton aggregation, or a feedback between zooplankton grazing and phytoplankton concentration. (2) In the Reduced-denitrification (RD) configuration, denitrification in the OMZ is reduced to 1/5 of the rate of the STD configuration following the procedure applied in the global biogeochemical circulation model by Schmittner et al. (2008). When oxygen is exhausted in the OMZ, denitrification within the UM box will then be responsible for only 1/5 of the remaining organic matter remineralization and the remainder will be remineralized in the D box (Eqs. B7 and B8). (3) The Ventilation-D (VD) configuration modifies the QM configuration in that the southern boundary of the model domain is partially opened to allow ventilation of O_2 and ^{14}C (but not NO_3^- and PO_4^{3-}) to the D box from the southern subtropical ocean (Eq. A7). The circulation parameters were recalibrated to account for ventilation of ^{14}C from the south. Ventilation is simulated by applying lateral mixing with the subtropical oligotrophic ocean tracer reservoir with prescribed ^{14}C and O_2 concentrations inferred from observations. All other biogeochemical processes within the model domain are kept the same as in the QM configuration. (4) In the Ventilation-D + Reduced-denitrification (VDRD) configuration, the reduced denitrification rate is applied in the VD configuration. (5) In the Ventilation-ID (VID) configuration, the partially open southern boundary is extended to allow ventilation of O_2 and ^{14}C also into the I box from the subtropical ocean (Eq. A6). Again, circulation parameters are recalibrated against observed $\Delta^{14}\text{C}$ taking into account the ^{14}C exchange between the subtropical ocean and the I and D boxes. (6) In the Ventilation-ID + Reduced-denitrification (VIDRD) configuration, the reduced denitrification rate is also applied in the VID configuration. (7) In the Open-boundary (OB) configuration, nutrient mixing is added to the VID configuration to allow for exchange of nutrients between the I and D boxes and the subtropical ocean. (8) In the Open-boundary + Reduced-denitrification (OBRD) configuration, the reduced-denitrification

Interactive Discussion

rate is again added to the OB configuration. The physical transports of NO_3^- and PO_4^{3-} for the I and D boxes in the last six configurations are represented by Eqs. (A6) and (A7) in Appendix A.

For the OBRD configuration, sensitivity experiments are performed in which the mixing rates with the southern boundary, K_H , is reduced for individual tracers (nutrients, oxygen) or combinations thereof from full rates to zero. To explore the sensitivity with respect to the circulation parameters of the box model, simulations of the OBRD configuration were repeated with individual circulation parameters varied by $\pm 10\%$, $\pm 20\%$ and $\pm 50\%$, respectively. The sensitivity of NO_3^- and O_2 concentrations in the OMZ to different physical parameters derived from variations of the $\Delta^{14}\text{C}$ data and O_2 concentrations in the U-box is also examined.

3 Results

The physical circulation parameters calibrated with $\Delta^{14}\text{C}$ are given in Table 4. The resulting circulation is comparable with our expectations for the upwelling region of the Eastern Tropical South Pacific. The parameters of the biogeochemical model are shown in Table 5.

3.1 Biogeochemical tracer concentrations

Nutrient and oxygen concentrations in the upwelling region (boxes U and UM) are influenced by physical exchange with regions outside the upwelling zone (boxes I and D) and subsequent remineralization of exported organic matter. In the STD configuration, NO_3^- levels in the UM box are quickly exhausted by denitrification in the UM box (black bars in Fig. 2), where decomposition of exported organic matter consumes all O_2 entering the UM box via advection and diffusion, and all NO_3^- entering via physical transport and remineralization of exported organic matter. In the STD configuration, O_2 is also depleted in the D box, owing to weak ventilation. This results in over 90 % of the initial

Interactive Discussion

nitrate being lost from the model domain by denitrification once the model has reached steady state. The large nitrate deficit with respect to phosphate in the upwelling waters results in nitrogen fixers becoming dominant in the U box despite having a lower maximum growth rate than ordinary phytoplankton. Ordinary phytoplankton and nitrogen fixers become almost extinct in the S box because of severe nutrient limitation.

In the QM configuration, ordinary phytoplankton and nitrogen fixers persist in box S (grey bars in Fig. 2). The quadratic mortality reduces mortality at low phytoplankton concentrations and thereby prevents extinction of ordinary phytoplankton in the open ocean. Still, the main problems remain, i.e., nitrate vanishes in the UM box, the D box becomes anoxic, and more than 90 % of the initial NO_3^- is lost.

In the RD configuration, complete NO_3^- exhaustion in the UM box is prevented (bars with horizontal lines in Fig. 2). There is some observational evidence for the efficiency of decomposition of organic matter driven by denitrification in some high-productivity areas being lower than for respiratory processes in the presence of sufficient dissolved oxygen (Liu and Kaplan, 1984; Van Mooy et al., 2002). In our model, this mechanism helps preventing NO_3^- depletion in the OMZ because less nitrate is consumed by denitrification during the passage of the particles through the OMZ. However, the additional organic matter now passing through the OMZ must be remineralized in the D box, which still becomes anoxic in this configuration.

The VD configuration, which supplies additional O_2 from the subtropical ocean into the D box, avoids anoxic deep waters, but fails to prevent nitrate exhaustion in the UM box (Fig. 8). The I and D boxes are oxic at steady state, but NO_3^- is still exhausted by denitrification in the UM box. Comparing the oxygen concentrations of the RD configuration and VD configuration, we conclude that ventilation helps to prevent oxygen depletion in the D box, but this mechanism alone cannot prevent eventual run-away denitrification in the UM box. After incorporating reduced denitrification rate in the VDRD configuration, nitrate depletion is prevented and the I and D boxes are oxic (bars with vertical lines in Fig. 2). But the O_2 concentration in the I box is about 28 % lower than

Interactive Discussion

that of the WOA2009 data, which indicates that O_2 supply into the D-box only may not be enough to ventilate the model domain.

The VID configuration, in which O_2 ventilation into the I box is also incorporated in addition to the D box, fails in preventing NO_3^- depletion by denitrification in the OMZ (Fig. 8). Several sensitivity experiments were performed to explore how NO_3^- depletion in the UM box can be prevented in the VID configuration. Decreasing the fraction for export production remineralized in the UM box (f_{UM}) from 70 % to 56 % makes NO_3^- persist in the UM box. Together with the 20 % remineralization in the U box, this implies that 76 % of the export production is remineralized in the upper 500 m of the ocean. However, the NO_3^- concentration in the UM box is only $3.8 \mu\text{mol kg}^{-1}$, far away from the literature range from about 15 to $40 \mu\text{mol L}^{-1}$. Next, a model of nitrogen fixation with an inverse relationship between NO_3^- concentration and the fraction of fixed nitrogen from nitrogen fixation (Holl and Montoya, 2005; Mills and Arrigo, 2010) was implemented. This approach inhibits nitrogen fixation in an environment with high NO_3^- concentrations, but fails to prevent NO_3^- depletion in the UM box.

After reducing the denitrification rate in the OMZ, which is the configuration denoted as VIDRD, NO_3^- depletion is prevented (bars with oblique lines in Fig. 2). Compared with the VDRD configuration, O_2 concentrations in the I box increase by about 21 %, closer to the WOA2009 data, however, O_2 concentration in the D box decreases due to a higher upwelling rate $A + B$ and slightly lower O_2 ventilation rate K_H (Table 4).

In the OB configuration, nutrients are exchanged in addition to O_2 between the subtropical ocean and the I and D boxes. In this configuration, nitrate exhaustion in the OMZ is still not prevented even though there are lower phytoplankton and nitrogen fixer concentrations in the surface U and S boxes (Fig. 8). Again, after reducing the denitrification rate under suboxic conditions in the OBRD configuration, N_{UM} depletion is prevented and N_{UM} approaches a concentration of $20 \mu\text{mol kg}^{-1}$ at steady state (bars with dots in Fig. 2). The UM box is suboxic and the O_2 concentrations in the I and D boxes agree very well with the WOA2009 data (gridded bars in Fig. 2). Overall, tracer

distributions simulated by the OBRD configuration agree best with the observations compared with other configurations.

3.2 Biogeochemical fluxes

For the biogeochemical fluxes, we will focus on the model configurations in Fig. 3, since they represent the most important mechanisms in preventing NO_3^- exhaustion in the OMZ. The STD and QM configurations display very similar biogeochemical fluxes because the physical parameters in the two configurations are the same (black and grey bars in Fig. 3 respectively). However, denitrification rates are higher in the STD and QM configurations than in the RD configuration (bars with horizontal lines in Fig. 3), even though the physical parameters are the same in all three configurations, leading to nitrate exhaustion in the UM box of the STD and QM configurations but not in the RD configuration. In the VDRD configuration, NO_3^- depletion is prevented (bars with vertical lines in panel E of Fig. 2). Compared with the VDRD configuration, the VIDRD configuration has a slightly higher denitrification rate and aerobic respiration rate in the OMZ because the altered transport parameters allow for a somewhat higher export production into the OMZ. Denitrification is weaker in the OBRD configuration than in the VIDRD configuration (bars with oblique lines in Fig. 3), even though the physical parameters are the same in both configurations, keeping more NO_3^- in the UM-box in the OBRD configuration (bars with dots in Fig. 3). Aerobic respiration in the UM box continues even when the UM box is anoxic. It consumes all O_2 entering the UM box via the various physical transport processes and thereby oxidizes respectively about 9.9 %, 8.7 %, 64 %, 87 %, 85 % and 92 % of the organic matter remineralized (denitrification+ aerobic respiration) in the UM box in all six configurations. Aerobic respiration is increased in the OBRD configuration compared with the VIDRD configuration (92 % vs. 85 %) at the expense of denitrification.

Compared with the VIDRD configuration, total PO_4^{3-} in the model domain decreases by about 28 % in the OBRD configuration at steady state, and the net PO_4^{3-} flux out

Interactive Discussion

of the I box and the corresponding net flux of PO_4^{3-} from the subtropical ocean into the D box causes a 9.6 % decrease in organic matter exported into the UM box. This explains why NO_3^- concentrations in the OMZ and O_2 concentrations in the I and D boxes are slightly higher (bars with oblique lines and bars with dots in Fig. 2). Restricting exchange with the subtropical oligotrophic ocean to NO_3^- and O_2 cannot result in higher O_2 concentrations in the I and D boxes, because it does not reduce the export production to be decomposed there. Restricting exchange to PO_4^{3-} and O_2 depresses production and organic matter decomposition by almost the same amount as in the model run that exchanges NO_3^- , PO_4^{3-} and O_2 , and succeeds in driving O_{21} and O_{2D} concentrations closer to the observations (not shown). Thus, opening the model boundary to PO_4^{3-} and O_2 helps to improve the behaviour of VIDRD configuration by depressing biological production in the upwelling region.

The fluxes associated with the fixed-N cycle in the OMZ of the OB configuration are compared with those of other models in Table 6. Our simulated export production and aerobic remineralization are mostly consistent with the results of Kalvelage et al. (2013), but our simulated anaerobic remineralization and fixed-N loss in the OMZ are much lower. However, our model's fixed-N loss due to denitrification is between the values reported by Mills and Arrigo (2010) and Kalvelage et al. (2013). The Kalvelage et al. (2013) model has much higher fixed-N influx into the OMZ via physical transport, which could compensate for their more intense NO_3^- loss in the OMZ.

In sensitivity experiments designed to elucidate the importance of the influence of the subtropical ocean on the model domain, we reduce the mixing rates (K_H) of O_2 , NO_3^- and PO_4^{3-} across the southern boundary in different combinations (Fig. 4). Total net primary production (NPP) is the same when varying the mixing rate of either only O_2 or O_2 together with NO_3^- , as long as the PO_4^{3-} exchange rate with the subtropical ocean remains unchanged (dotted lines in Fig. 4b and g). The reason is that changes in nitrate exchange with the subtropical ocean are compensated by changes in denitrification and nitrogen fixation. This implies that NPP is, at steady state, determined only by phosphate availability. Once the total NPP of NF and Phy is determined by

Interactive Discussion

PO_4^{3-} supply, aerobic respiration will increase with increasing O_2 supply, while anaerobic remineralization will decrease (solid lines in Fig. 4c and h). Comparing simulations that vary the mixing rate of O_2 together with that of PO_4^{3-} , with simulations that vary the mixing rate of O_2 together with that of NO_3^- and PO_4^{3-} (dotted lines in Fig. 4l and q) reveals that the combined NPP of Phy and NF decreases with decreasing PO_4^{3-} inventory at low mixing rates and increases with increasing PO_4^{3-} inventory at high mixing rates, irrespective of NO_3^- mixing rate.

It turns out that NO_3^- depletion in the OMZ is prevented in the four sensitivity experiments of Fig. 4 no matter how much O_2 is supplied from the subtropical ocean into the model domain. But anoxia in the D box can only be prevented if the external O_2 supply can oxidise more than about 20 % export production in the model domain (solid lines in Fig. 4e, j, o and t). These experiments also reveal an interesting link among the O_2 supply from the subtropical ocean, the nitrate concentration in the OMZ, and the NO_3^- flux between the model domain and surrounding ocean. As soon as the O_2 supply from the subtropical ocean accounts for about 17.5 % of the respiratory O_2 consumption, the model domain turns into a small net source of fixed-N (dashed lines in the first row of Fig. 4). Once anoxia is prevented in the D box, the nitrate concentration in the OMZ (UM box) increases quite strongly from about $15 \mu\text{mol kg}^{-1}$ to reach about $20 \mu\text{mol kg}^{-1}$ at full mixing strength.

The behaviour of the model domain as a small pelagic net NO_3^- source in the OBRD configuration is rather insensitive to the physical transport parameters (Fig. 5). The model domain remains a net NO_3^- source even when the physical transport parameters are varied by up to $\pm 50\%$. The finding that the model domain is a net NO_3^- source is also tenable for all suites of physical transport parameters in the literature range for which the D-box is oxic (Fig. 7).

The oxygen concentrations in the UM, I and D boxes increase in sensitivity model runs with physical parameters calibrated from increased ^{14}C concentrations (lower water mass age). NO_3^- depletion is prevented in the OMZ in the OBRD configuration within

Interactive Discussion

the range of about $\pm 10\%$ around the default ventilation intensity (Fig. 6a). The UM box remains anoxic when $\Delta^{14}\text{C}$ is varied within this range, which indicates that this mechanism for preventing NO_3^- depletion in the OMZ may be robust against modest changes in the regional ocean circulation patterns. Meanwhile, NO_3^- and O_2 in the UM box are quite insensitive to the O_2 concentration in the U-box for this configuration (Fig. 6b).

4 Discussion and conclusions

Nitrogen is often considered to be the primary limiting nutrient in marine upwelling regions with OMZs (Cline and Richards, 1972; Codispoti and Christensen, 1985; Morrison et al., 1998; Voss et al., 2001), where denitrification rates can be high and are generally thought to cause a major loss of fixed-N from the world ocean. The nitrogen deficit is commonly assumed to stimulate N_2 fixation, both in observational estimates of N_2 fixation (Deutsch et al., 2007; Monteiro et al., 2010) and in current descriptions of N_2 fixation in biogeochemical models (Moore and Doney, 2007; Schmittner et al., 2008). However, if N_2 fixation is tightly linked to nitrogen loss processes, denitrification of organic matter derived from N_2 fixation can consume more nitrogen than was fixed via N_2 fixation and thereby lead to a vicious cycle of run-away nitrogen loss (Landolfi et al., 2013). This has been found to lead to total depletion of NO_3^- in the OMZ of box models (Canfield, 2006) and global biogeochemical circulation models (Moore and Doney, 2007; Schmittner et al., 2008). For our fully prognostic 5-box model, we have identified the mechanisms capable of arresting the run-away nitrogen loss that can result from a close coupling of nitrogen fixation and denitrification (Landolfi et al., 2013) and maintaining realistic non-zero NO_3^- concentrations in open-ocean OMZs of the ETSP: reduced NO_3^- consumption by denitrification owing to slower remineralization under suboxic compared to oxic conditions, coupled with lateral ventilation between the model domain and an ocean basin outside of the model domain (the subtropical ocean in this case).

Interactive Discussion

In this work, the model configuration with reduced denitrification rate and lateral ventilation and nutrient exchange (OBRD configuration) behaves most reasonable, whereas reduced rates of denitrification alone leads to unrealistic O_2 depletion in the deep waters, and reduced rates of denitrification combined with only O_2 ventilation in the D or both I and D boxes configurations do worse in fitting the WOA2009 data for O_2 in the I and D boxes. By allowing for exchange of O_2 and nutrients with the subtropical ocean in the OBRD configuration, the delicate balance between sufficient O_2 supply required for maintaining high levels of aerobic respiration and sufficient PO_4^{3-} loss through the open boundary appears fulfilled. Compared with other box models (Shaffer and Sarmiento, 1995; Tyrrell, 1999; Deutsch et al., 2004; Canfield, 2006; Mills and Arrigo, 2010; Eugster and Gruber, 2012; DeVries et al., 2012), the box model we use here explicitly employs both a reduced-denitrification rate and an open boundary condition, which seems to be a prerequisite for the ability to simulate realistic nitrate conditions in the OMZ and oxygen concentrations in the adjacent ocean.

Phosphate turns out as the ultimate limiting nutrient in our model (second and forth rows of Fig. 4), and hence determines the nitrogen content of the OMZ. This strong control of phosphate on the N cycle is similar to the finding of previous studies (e.g. Lenton and Watson, 2000; Canfield, 2006), where the occurrence and extent of oceanic anoxia was also tightly linked to phosphate supply. These studies explicitly assumed that N_2 fixation acts to restore surface-oceanic dissolved inorganic N : P ratio towards the Redfield ratio. By contrast, we do not prescribe the effect of nitrogen fixation on surface inorganic nutrients, and the finding of phosphate as the ultimate limiting nutrient is obtained regardless of whether NF responds directly to the N : P ratio in the surface ocean or whether NF is inhibited by the presence of NO_3^- (see Appendix D).

Even though our model indicates only a weak dependence of simulated NO_3^- concentrations in the OMZ on the lateral O_2 supply from the subtropical ocean, O_2 depletion in the adjacent ocean can be prevented only when the O_2 supply from the subtropical ocean accounts for more than 20 % of the O_2 required to oxidize export production from the surface ocean of our model domain (U and S boxes). This value only varies

from about 17 % to 23 %, when the size of the S box varies by $\pm 50\%$, indicating that our above conclusion is insensitive to our choice for the model domain. The O_2 supply from the subtropical ocean might be also linked to the balance of the regional fixed-N cycle. In the most realistic (OBRD) configuration, the balance of water-column denitrification and nitrogen fixation is tightly linked to the nitrate concentration in the OMZ: if the model domain acts as a sink for fixed-N, nitrate concentrations in the OMZ do not exceed about $15 \mu\text{mol kg}^{-1}$, i.e., the lower limit of current observations, 15 to $40 \mu\text{mol kg}^{-1}$ (Codispoti and Richards, 1976; Codispoti and Packard, 1980; Morrison et al., 1998; Voss et al., 2001). Nitrate concentrations close to those commonly found in OMZs are predicted only when nitrogen fixation exceeds water-column denitrification and the ocean basin containing the OMZ becomes a net source of fixed-N (first row of Fig. 4).

There are no specific data or model results focusing on the water-column nitrogen balance of the ETSP. Our simulations using a parameterisation where nitrogen fixation is inhibited by the presence of nitrate yield very similar results, only with slightly reduced nitrogen fixation resulting in a somewhat reduced (by $\leq 15\%$) nitrogen source for strong enough lateral oxygen supply. Ganachaud and Wunsch (2002) estimated a net northward NO_3 transport of $270 \pm 170 \text{ kmol s}^{-1}$ ($119.2 \pm 75.1 \text{ Tg N yr}^{-1}$) across 17°S into the ETSP indicating that the ETSP is a net nitrogen sink, but their estimate included benthic denitrification, which is not accounted for in our current analysis. In a model-guided analysis, DeVries et al. (2012) predicted water-column denitrification rates of $21\text{--}33 \text{ Tg N yr}^{-1}$ by simulating the distribution of observed dissolved N_2 gas produced by denitrifying bacteria. From an analysis of nutrient concentrations and transport rates, Deutsch et al. (2007) estimated nitrogen fixation rates in the Pacific Ocean of about 95 Tg N yr^{-1} , half of which was speculated to occur in the ETSP. From these estimates, we cannot rule out that the water column of the ETSP is a net source of fixed-N, which would be consistent with our results obtained in the OBRD configuration. More recently, Eugster and Gruber (2012) probabilistically estimated nitrogen fixation and water-column and benthic denitrification separately, and we find that the

Interactive Discussion

water column of the IndoPacific is a large fixed-N source when we estimated the fixed-N budget for that regions, which appears to be consistent with our results.

Based on our model results, we conclude that reduced NO_3^- consumption by denitrification owing to slower remineralization under suboxic conditions together with lateral transport is essential to arrest the vicious cycle of run-away fixed-N loss in the OMZ. More research is needed to better constrain the model parameters, in particular the upwelling transport and the difference between the organic matter remineralisation rate via aerobic respiration and anaerobic denitrification.

Appendix A:

Physical transports of a tracer X among the boxes U, UM, S, I, and D are defined for the STD configuration as follows:

$$\text{Transport}(X_U) = (X_{UM} - X_U)(A + B + K_{US}) \cdot L_U \quad (\text{A1})$$

$$\begin{aligned} \text{Transport}(X_{UM}) = & [AX_D + BX_I - X_{UM}(A + B) + K_{US}(X_U - X_{UM})] \cdot L_U \\ & + K_{UM}(X_D - X_{UM}) \cdot L_U + K_H(X_I - X_{UM}) \cdot H_{UM} \end{aligned} \quad (\text{A2})$$

$$\text{Transport}(X_S) = (A + B)(X_U - X_S) \cdot L_U + K_{US}(X_I - X_S) \cdot L_S \quad (\text{A3})$$

$$\begin{aligned} \text{Transport}(X_I) = & (A + B)(X_S - X_I) \cdot L_U + K_H(X_{UM} - X_I) \cdot H_{UM} \\ & + K_{US}(X_S - X_I) \cdot L_S + K_{UM}(X_D - X_I) \cdot L_S \end{aligned} \quad (\text{A4})$$

$$\text{Transport}(X_D) = A(X_I - X_D) \cdot L_U + K_{UM}(X_{UM} - X_D) \cdot L_U + K_{UM}(X_I - X_D) \cdot L_S \quad (\text{A5})$$

For the VD, VDRD, VID, VIDRD, OB and OBRD configurations, Eqs. (A4) and (A5) are modified to read:

$$\begin{aligned} \text{Transport}(X_I) = & (A + B)(X_S - X_I) \cdot L_U + K_H(X_{UM} - X_I) \cdot H_{UM} \\ & + K_{US}(X_S - X_I) \cdot L_S + K_{UM}(X_D - X_I) \cdot L_S \\ & + K_H(X_{SI} - X_I) \cdot H_{UM} \end{aligned} \quad (\text{A6})$$

$$\text{Transport}(X_D) = A (X_I - X_D) \cdot L_U + K_{UM}(X_{UM} - X_D) \cdot L_U + K_{UM}(X_I - X_D) \cdot L_S + K_H(X_{SD} - X_D) \cdot H_D \quad (\text{A7})$$

The transport equations (Eqs. A1 and A3) are modified for Phy and NF because Phy and NF are assumed to be capable of regulating their buoyancy and exist only in U and S without being transported vertically between the U and UM or the S and I boxes.

Appendix B:

The nitrogen cycle in this model includes nitrogen fixation, denitrification, inorganic nitrogen regeneration by remineralization, and physical transport of nitrogen. The physical transport process of NO_3^- is the same as for other tracers. Rem_i^N represents nitrogen remineralization in box i with fixed fractions f_i of the net primary production in the overlaying surface boxes.

$$\text{Rem}_U^N = f_U M(\text{Phy}_U + \text{NF}_U) \cdot H_U \cdot L_U \quad (\text{B1})$$

$$\text{Rem}_{UM}^N = f_{UM} M(\text{Phy}_U + \text{NF}_U) \cdot H_U \cdot L_U \quad (\text{B2})$$

$$\text{Rem}_S^N = f_S M(\text{Phy}_S + \text{NF}_S) \cdot H_U \cdot L_S \quad (\text{B3})$$

$$\text{Rem}_I^N = f_I M(\text{Phy}_S + \text{NF}_S) \cdot H_U \cdot L_S \quad (\text{B4})$$

$$\text{Rem}_D^N = M \left[(1 - f_U - f_{UM})(\text{Phy}_U + \text{NF}_U) \cdot L_U + (1 - f_S - f_I)(\text{Phy}_S + \text{NF}_S) \cdot L_S \right] \cdot H_U \quad (\text{B5})$$

Denitrification (Denif) is the nitrogen loss to N_2 when UM, I and D are anoxic. It is defined as:

$$\text{Denif}_i = \max\left(\text{Rem}_i^N - \frac{\text{Res}_i}{r_a}, 0\right) \cdot \frac{r_c}{r_{\text{den}}} \quad i \in [\text{UM}, \text{I}, \text{D}] \quad (\text{B6})$$

Interactive Discussion

with the aerobic respiration term Res_i given below (Eq. B10). In the RD, VDRD, VIDRD and OBRD configuration, the equations for denitrification in the i box and remineralization in D are given by:

$$\text{Denif}_i = \frac{1}{5} \cdot \max(\text{Rem}_i^N - \frac{\text{Res}_i}{r_a}, 0) \cdot \frac{r_c}{r_{\text{den}}} \quad i \in [\text{UM}, \text{I}] \quad (\text{B7})$$

$$\begin{aligned} \text{Rem}_D^N = & M[(1 - f_U - f_{\text{UM}})(\text{Phy}_U + \text{NF}_U) \cdot L_U + (1 - f_S - f_I)(\text{Phy}_S + \text{NF}_S) \cdot L_S] \cdot H_U \\ & + 4 \cdot \frac{\text{Denif}_i \cdot r_{\text{den}}}{r_c} \quad i \in [\text{UM}, \text{I}] \end{aligned} \quad (\text{B8})$$

All the organic matter is composed according to the Redfield Ratio, i.e., C : N : P = 106 : 16 : 1. Rem_i^P represents phosphate remineralization in box i , which is obtained by dividing Rem_i^N by the Redfield N : P ratio, r_p :

$$\text{Rem}_i^P = \frac{\text{Rem}_i^N}{r_p} \quad i \in [\text{U}, \text{S}, \text{UM}, \text{I}, \text{D}] \quad (\text{B9})$$

Respiration (Res_i) is considered in the intermediate and deep ocean. In the presence of sufficient oxygen or when oceanic circulation supplies enough O_2 , organic matter will be preferentially oxidized by respiration. We use a ratio of $-\text{O}_2$: N = 170 : 16 during oxic remineralization of organic matter (Anderson and Sarmiento, 1994).

$$\text{Res}_i = \begin{cases} r_a \cdot \text{Rem}_i^N & \text{if } \text{O}_{2i} > 0 \\ \min(\text{Transport}(\text{O}_{2i}), r_a \cdot \text{Rem}_i^N) & \text{if } \text{O}_{2i} = 0 \end{cases} \quad i \in [\text{UM}, \text{I}, \text{D}] \quad (\text{B10})$$

Appendix C:

Transport and SMS terms for ^{14}C constitute a system of 5 linear equations including transport parameters A , B , K_{US} , K_{UM} and K_{H} , which are inverted from the $\Delta^{14}\text{C}$ values with air-sea $\Delta^{14}\text{C}$ exchange rates g_U and g_S for the U and S boxes respectively.

Interactive Discussion

g_U and g_S were constrained in a two-step procedure. First, all combinations are determined which result in transport parameters in the literature range in Table 5. Finally, the combination giving the most realistic biogeochemical tracer concentrations (closest to observations) is chosen for the experiments in the main text (Fig. 8). This approach for determining the physical transport parameters is applied to obtain the ones in Table 4.

Appendix D:

It is well known from laboratory studies that diazotrophic phytoplankton can also utilize nitrate for growth (e.g., Holl and Montoya, 2005). Schmittner et al. (2008) introduced a formulation where nitrogen fixers preferentially use nitrate when available and cover only the residual nitrogen demand via N_2 fixation. In order to examine the behavior of our model when nitrogen fixers (NF) preferentially use nitrate, nitrogen fixation is separated from diazotroph growth, as in Schmittner et al. (2008):

$$\text{Nitrogen-fixation}_i = \left(1 - \frac{N}{N + N_h}\right) \cdot \text{NPP}^{\text{NF}_i} \quad i \in [U, S] \quad (\text{D1})$$

and Eq. (6) was modified to accommodate the additional nitrate uptake by NF as follows:

$$\text{SMS}(N_i) = \left(-\text{NPP}^{\text{Phy}_i} - \left(\text{NPP}^{\text{NF}_i} - \text{Nitrogen-fixation}_i\right)\right) \cdot V_i + \text{Rem}_i^N - \text{Denif}_i$$

$$i \in [U, \text{UM}, S, I, D] \quad (\text{D2})$$

Model results for all configurations with Eqs. (D1) and (D2) are presented in Fig. 9. Compared to Fig. 2, this configuration behaves very similarly, except that Phy_U and Phy_S concentrations are somewhat lower because nitrogen fixers take up NO_3^- as well. Thus, we conclude that our results are robust with respect to assumptions about fixed-N usage by diazotrophs.

Table 4. Parameters of the physical model configurations.

Configuration	STD	VD VDRD	VID VIDRD OB OBRD	Units
K_{US}	8.44	3.37	3.41	m yr^{-1}
K_{UM}	1.59	0.40	0.58	m yr^{-1}
K_H	47 799	50 475	42 938	m yr^{-1}
A	7.20	7.30	7.22	m yr^{-1}
B	18.01	19.60	23.07	m yr^{-1}
g_U	9.87	8.89	9.88	m yr^{-1}
g_S	2.94	1.42	1.46	m yr^{-1}

Discussion Paper	Discussion Paper	Discussion Paper	Discussion Paper
------------------	------------------	------------------	------------------

^a Ranges for r_a , r_c , r_{den} , K_{US} , K_{UM} , K_H , A and B are the same as in Canfield (2006).
^b The fraction of regeneration above 500 m has been estimated between 92 % (Suess, 1980) and 97 % (Martin et al., 1987). According to Canfield (2006), most likely 60–70 % of the export production is remineralised in the OMZ. Thus, we define 20 % and 70 % of export production remineralised in the surface boxes and intermediate boxes respectively.
^c Furnas (1990)
^d Roberts and Zohary (1987); Capone et al. (1997)
^e Caron and Dennett (1999)
^f Palmer and Totterdell (2001); Schmittner et al. (2008)
^g Eppley et al. (1969)
^h McAllister et al. (1964)
ⁱ Average 0–100 m O_2 concentrations of the corresponding areas from World Ocean Atlas (2009).
^j Libby (1956)
^k Averages of the corresponding areas from World Ocean Atlas (2009).
^l These parameter values are defined in Table 4.

What prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific?

B. Su et al.

Figure 1. Model structure and configurations. The model domain comprises five active boxes representing the top 100 m of an upwelling region (U), the underlying oxygen minimum zone (UM), and an adjacent open-ocean basin divided into a surface (S) and an intermediate-depth box (I). A deep box (D) underlies both the upwelling region and the open ocean. The large-scale circulation is represented by deep (A) and shallow (B) convection (thick grey lines). Mixing between boxes is implemented via mixing coefficients (K). Remineralization derived from net primary production by ordinary (Phy) and diazotrophic (NF) phytoplankton in the surface boxes consumes oxygen. Under anoxic conditions remineralization is fueled by anaerobic remineralization (Denif). The model can be configured to exchange nutrients and oxygen with the southern subtropical ocean (right). See Table 5 for symbol definitions and text for details.

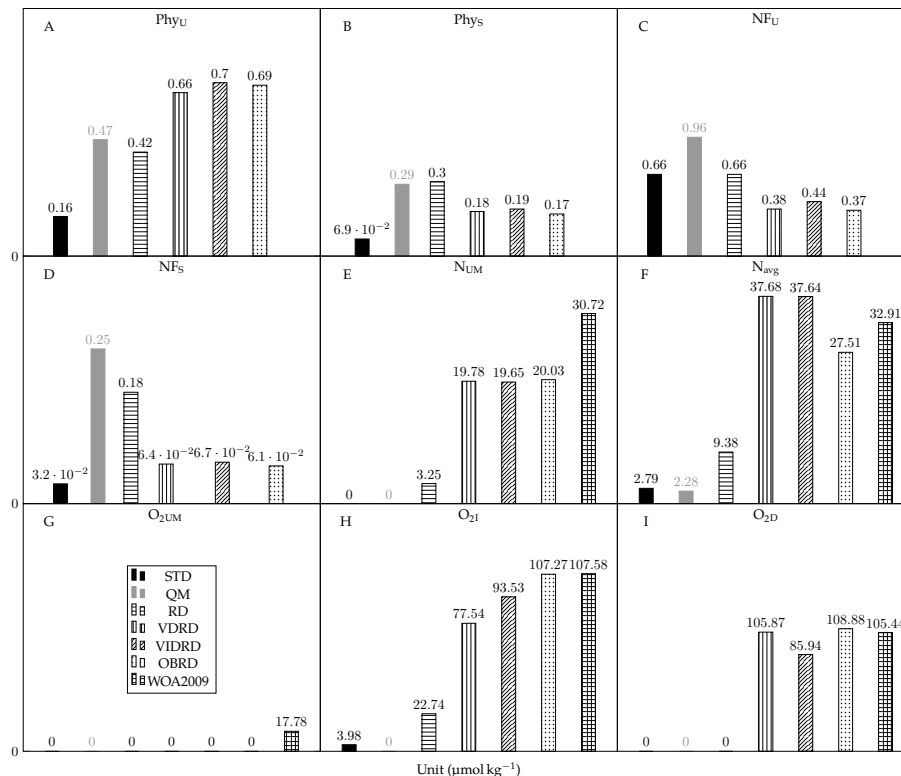

Figure 2. Simulated steady-state phytoplankton, nutrient and oxygen concentrations for the model configurations defined in Tables 3 and 4. Each panel uses linear scale of the y-axis starting at zero. Gridded panels represent the average of the WOA2009 data of the corresponding boxes, however, there are no data for Phy_U, Phy_S, NF_U and NF_S.

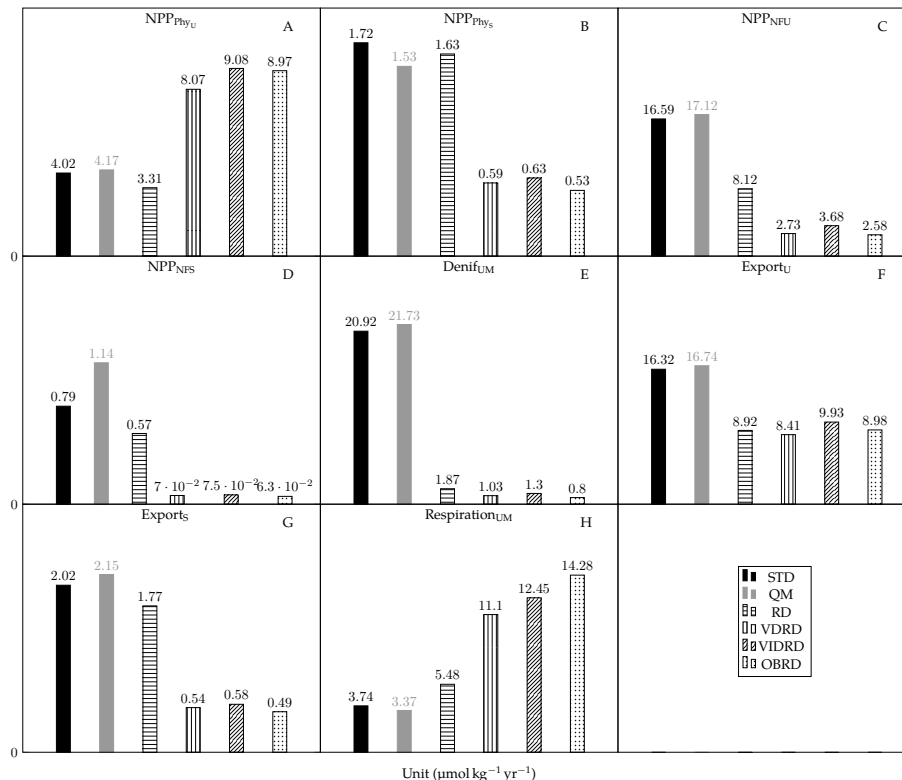

Figure 3. Simulated steady-state biogeochemical fluxes for the model configurations defined in Tables 3 and 4. NPP_{PhyU} , NPP_{PhyS} , NPP_{NFU} and NPP_{NFS} represent the net primary production rates of Phy_U , Phy_S , NF_U and NF_S respectively. $Denif_{UM}$ indicates the nitrogen loss rate by anaerobic remineralization in the UM box. $Export_U$ and $Export_S$ represent the export production rate out of U and S. $Respiration_{UM}$ represents aerobic respiration rate in the UM box. Note that all panels are in units of nitrogen except (**H**), which is in units of O_2 . Each panel uses a different linear scale for the y-axis starting at zero.

What prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific?

B. Su et al.

Figure 4. Dependence of the biogeochemical processes on the ratio of O_2 supply from the subtropical ocean and export production from the surface ocean (boxes U and S). N_{UM} and NO_3^- influx represent NO_3^- concentration in the UM box and NO_3^- flux from the southern boundary (positive into model domain). NPP_{Phy} , NPP_{NF} and NPP_{NF+Phy} are net primary production by ordinary phytoplankton, nitrogen fixers, and the sum of ordinary phytoplankton and nitrogen fixers in surface ocean. Respiration and denitrification (UM) represent O_2 consumption by aerobic remineralization and NO_3^- removal by anaerobic remineralization, respectively, in the UM box. N-inventory and P-inventory are the total nitrogen and phosphorus inventories in the model domain, including all the related organic and inorganic species. O_{2D} and denitrification (D) represent O_2 concentration and NO_3^- removal by anaerobic remineralization in the D box. Units of all the variables in this figure are $10^{11} \mu\text{mol yr}^{-1} \text{m}^{-1}$ except for N_{UM} and O_{2D} , which are given in $\mu\text{mol kg}^{-1}$. The shaded area denotes the parameter range for which the model domain is a net source of fixed-N.

Interactive Discussion

Figure 5. Sensitivity of the strength of the net NO_3^- flux out of the model domain for different variations of the individual parameters describing ocean transport (see Table 4 and Fig. 1 for a description of the parameters). The flux is normalized by the flux simulated by the OBRD model configuration.

What prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific?

B. Su et al.

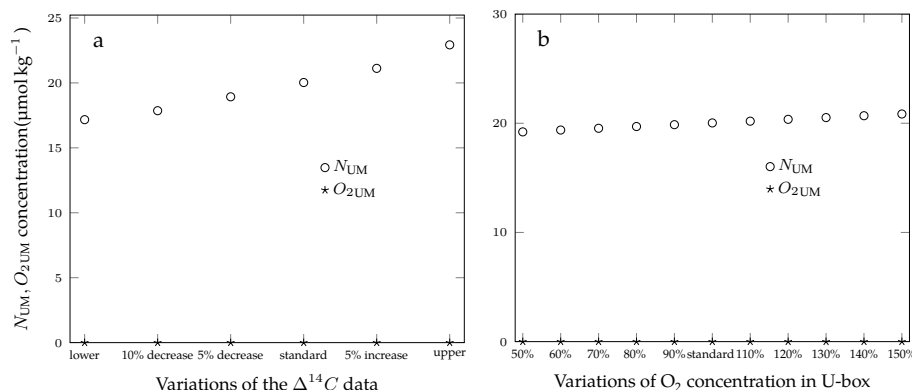

Figure 6. NO_3^- and O_2 concentrations in the OBRD configuration for different physical parameters derived from variations of the $\Delta^{14}\text{C}$ data **(a)** and O_2 concentration in U-box **(b)**. **(a)** Decrease and increase mean that $\Delta^{14}\text{C}$ values in all boxes are reduced or increased simultaneously. **(b)** Values of the x-axis denote the variations of O_2 concentration in the U-box relative to the standard. Standard run in each figure is the OBRD configuration with physical parameters defined in Table 4.

Figure 7. Lateral NO_3^- input into the model domain of the OBRD configuration. “Fluxes into the I box” represents lateral NO_3^- input into the I box; “fluxes into the D box” represents lateral NO_3^- input into the D box; “fluxes into the I and D boxes” is the sum of the above two processes. In this figure, negative values indicate that the model is a NO_3^- source, and positive values that the model is a NO_3^- sink instead.

What prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific?

B. Su et al.

Figure 8. NO_3^- concentration in the OMZ and O_2 concentrations in the I box for all combinations of physical transport parameters in the literature range. The x-axis is the O_2 concentration in the D box. Red dot in each panel is the selected suite of physical transport parameters which fit the biogeochemical data best in each model configuration. The horizontal green dashed lines represent the average of WOA2009 data for N_{UM} and $\text{O}_{2\text{I}}$, and the vertical green dashed lines denote the average of WOA2009 data for $\text{O}_{2\text{D}}$.

Interactive Discussion

What prevents nitrogen depletion in the OMZ of the Eastern Tropical South Pacific?

B. Su et al.

Figure 9. Same as Fig. 2 but with diazotrophs utilising also nitrate when available (Eqs. D1 and D2). Again, each panel uses a different linear scale for the y-axis starting at zero. Gridded panels represent the average of the WOA2009 data of the corresponding boxes, however, there are no data for Phy_U , Phys , NF_U and NF_S .
